Abstract

Torsion of the gallbladder is a relatively rare surgical disease which mimics acute cholecystitis' symptoms that usually would not be respondable to medical therapies. The torsion would mostly be diagnosed intra-operatively. Cholecystectomy is the treatment of choice. In general in our centre, General Surgery department, Imam Reza hospital, Mashhad, Iran, since 1986 over 14000 cholecystectomies have been performed and 3 cases with an underlying cause of gallbladder torsion are documented. The relative literatures reviewed so then the presentation, paraclinical findings, and the treatment of gallbladder volvulus are discussed. Gallbladder volvulus: Review of the literature and report of three cases.

Key Words: Gallbladder torsion; cholecystitis; cholecystectomy

Introduction

Torsion of the gallbladder is a relatively rare disease. The disease was first described in 1898 by Wendel 1. The true incidence is not known, but over 500 cases has been reported in the last century 2. It is generally due to abdominal anatomical fixation of the gallbladder and twisting axially. The clinical presentation and laboratory findings are the same as in acute cholecystitis. Treatment consists of detorsion and cholecystectomy. We present three cases of gallbladder volvulus and clinical aspects of the disease will be reviewed.

Cases

Case 1:
The first case is a 71 year old male with Coronary Artery Disease (CAD), suffering from right upper quadrant (RUQ) and epigastrium pain, nausea and vomiting for the last four days and a low grade fever; p physical examination revealed tenderness in epigastrium and RUQ. Other physical findings were in normal ranges. Leukocyte count was 13100/mm3, with neutrophils as high as 84%. Serum total and direct bilirubin were in normal ranges. Liver function tests were elevated; while alkaline phosphatase was 360IU/L.

The abdominal plain films were normal. Ultrasound examination showed a large distended gallbladder with a thickened wall (5 mm) and multiple stones. Assuming acute cholecystitis as the diagnosis, the intravenous fluid, broad spectrum antibiotic and analgesic were started. Eight hours after the admission his complaints of right upper quadrant pain and muscle guarding...

had been increased, despite analgesic therapies. Considering all these aforementioned facts along with the ultrasound findings, an emergent laparotomy was performed. At the operation he had a very large (13x8 cm), distended and gangrenous gallbladder that had rotated 180° counterclockwise. (fig.1,2,3) The mesentery of the gallbladder covered only the cystic duct and artery; and multiple large stones were found inside. The gallbladder was detorted and then excised. The pathologist reported a transmural gangrene of the gallbladder. The patient was discharged 6 days after the surgery.

Case 2:

A 67-year-old man was admitted to the emergency ward with right upper quadrant and epigastrium pain, nausea and vomiting which had been suddenly initiated 8 hours prior to the time. With the exception of tenderness in epigastrium and RUQ, other physical findings were normal. A leukocyte count of 12000/mm³ (PMN 94%), and normal serum total and direct bilirubin were his lab test results. The abdominal plain radiographies were normal. Ultrasound examination showed a large distended gallbladder with thickened wall (7mm) without any stones inside. Assuming acute cholecystitis as the diagnosis, intravenous fluid, broad spectrum antibiotics and analgesic were started. Because of the severe tenderness in his RUQ the patient underwent through an emergent laparatomy. The gallbladder has been rotated 180 degrees clockwise; therefore, after the detortion, it was excised. The patient was discharged 5 days after the surgery. The pathology report showed a transmural gangrene of the gallbladder.

Case 3:

A 56-year-old woman was admitted to the emergency ward with right upper quadrant and epigastrium pain, nausea and vomiting which had been suddenly initiated 15 hours prior to the time. With the exception of tenderness in RUQ, other physical findings were normal. The blood cell count and serum total and direct bilirubin were in normal ranges. The abdominal plain films were normal. Again, ultrasound examination showed a large distended gallbladder without any stones inside. In the same way, having acute cholecystitis as the initial diagnosis, intravenous fluid, broad spectrum antibiotics and analgesic were started. After 12 hours because of severe tenderness in RUQ,
an emergent laparotomy was performed. At the operation after detorting the distended gangrenous gallbladder, which had rotated 5270 counter-clockwise, a cholecystectomy was performed. The patient was discharged 6 days after the surgery. The pathologist reported a transmural gangrene of gallbladder.

**Discussion**

Generally over than 14,000 cholecystectomies have been performed since 1986 in our centre, out of which these 3 cases of gallbladder torsion have been documented. Volvulus is a twist of a non-solid organ over its mesenteric axis. The most common sources of volvulus are the sigmoid colon, cecum, and small intestine. It rarely occurs in the stomach. Gallbladder volvulus is an extremely rare disease in which immediate surgical intervention would be lifesaving. It was first described by Wendel in 1898. The true incidence is not exactly known. Eighty-five percent of gallbladder volvulus cases occur between the ages of 60 and 90 years, with a female-to-male ratio of 3:1, although this ratio has turned to be 1:2 in our study. Etiologically, the mechanisms leading to the torsion are poorly understood. While largely acquired and secondary to aging, GT may also be congenital. Three anatomic variants are thought to be responsible for the torsion 1, 6, 7. The first one is due to a “free-floating gallbladder” suspended only by the cystic mesentery in which cystic artery acts as a vascular axis. The second one describes the gallbladder when it is hanging from the liver through an elongated, narrow-based and freely mobile mesentery due to age-related visceropexy. The rotation occurs around an axis represented by the gallbladder itself or its liver mesentery. An extremely rare third variant consists of a normally fixed gallbladder to a mobile liver lobe free of its coronary and triangular ligaments.

Loss of fat and the liver atrophy that may occur with advancing age can cause an acquired elongated, narrow based gallbladder mesentery. Other precipitating factors are violent peristalsis of the neighboring organs, namely stomach, duodenum and colon, kyphosis, visceropexy, atherosclerosis of the cystic artery, weight loss, constipation or diarrhoea, sigmoid volvulus, obesity, or even iatrogenic manipulation, intense gastric and duodenal peristalsis which will supposedly cause a clockwise torsion (51%). Peristalsis of the colon on the other hand can lead to a counterclockwise rotation (31.8%) and volvulus of the gallbladder 14, 15. In our study two of the torsions were counterclockwise. Torsion of the gallbladder presents as an acute cholecystitis which fails to improve by conservative treatments.

This was the main clinical picture in all of our three patients. Surgeons should have high index of suspicion for a gallbladder volvulus and so proceed with prompt surgical treatment. An apt preoperative diagnosis of GT would rarely be made. Clinical symptoms would be nonspecific and include abdominal pain (100%), nausea and vomiting (52.7%) palpable mass (32.6%), fever (31.8%) and jaundice (0.8%) 15. If gangrene has already occurred, fever, peritonitis and ileus might also be present. If there would be an associated choledocholithiasis, or a direct compression of the common bile duct by the volvulated gallbladder, symptoms and signs related to cholestasis should occur.

Physical examination, which are sometimes unremarkable, usually shows non-specific right-sided findings such as guarding, tenderness, and low-grade fever. In 54% of cases a palpable gallbladder exists.

Laboratory investigations are not usually helpful. An elevated white blood cell count would be a frequent finding. Liver function tests are commonly normal. Approximately 70-80% of patients with torsion have no gallstones. Although the importance of gallstones is unknown, but their presence may not play an important role in developing the gallbladder torsions 15. Volvulus interferes with blood supply and bile flow. Consequently, gallbladder wall thickening, hydrops, and finally, gangrene will develop. Ultrasonography most frequently reveals “cholecystitis” with or without cholelithiasis. A typical “square” gallbladder, which is largely scaled anteriorly and floats without gallstones, or a gallbladder outside its fossa, inferior to the liver, in a transverse orientation, with an echogenic conical structure (the twisted pedicle), is rarely seen on Ultrasonographies 7, 19.

Computed tomography scan provides similar diagnostic clues with ultrasonography which will be as the followings: the presence of gallbladder outside its fossa and inferior to the liver, pericholecystic fluid, and massively distended gallbladder with its wall thickened. Color Doppler sonography would be helpful in differentiating the diagnoses by the mean of evaluating the gallbladder’s wall blood flow. Blood flow would not be detectable in a torsive gallbladder, whereas the cystic artery along the wall could be visualized in an acute cholecystitis 15. A hydroxyiminodiacetic acid (HIDA) scans may...
Endoscopic retrograde floating gallbladder mostly in the 7th and 8th decades of life. With a high index of suspicion, it can be diagnosed preoperatively by an ultrasonography. Laparoscopic cholecystectomy is feasible, safe and advisable, allowing a faster recovery and shorter hospital stay comparing to conventional cholecystectomy.
